Image Interchange Framework Subcommittee

Version 1.1   November 18, 2010

Summary: The Academy Density Exchange Encoding (ADX) is an RGB density encoding of motion picture color negative film image data within the Academy's Image Interchange Framework. Academy Printing Density (APD) is the optical density of the motion picture film material as seen by the material onto which the film material is printed. This document specifies 10-bit integer and 16-bit integer ADX encodings. Also specified are the spectral responsivities that define the APD printing density metric that serves as the basis for the encoding method of the ADX encodings. ADX and APD are designed for use with color negative and internegative film materials, color process control hardware, color film scanners, and film recorders common to the motion picture industry. This specification also describes a method for converting ISO Status M density to APD.

Introduction

Academy Density Exchange Encoding (ADX) is the common densitometric encoding of scanned motion picture color negative film images used within the Academy's Image Interchange Framework (IIF). Academy Printing Density (APD) specifies a printing density definition appropriate for use with motion picture negative and internegative films and serves as the basis for the density encoding method of ADX. ADX values may encode densitometric imagery in a form suitable for transformation into Academy Color Encoding Specification (ACES) values for creative manipulation. Later points in the image processing chain provide forms suitable for critical viewing (Figure 1).
Figure 1 – Abridged IIF Image Processing Diagram

The spectral responsivities that define APD, known as Π_{APD} and provided in Annex A, are based on the spectral sensitivities of contemporary motion picture print films such as those of the Kodak Vision family, of the Fujifilm Eterna family, and of Fujifilm F-CP. Its definition is also based on the spectral power distribution of a Bell & Howell Model C printer lamp house with dichroic filters and the spectral transmission of an Eastman Kodak Wratten Filter No. 2B. As such, the spectral responsivities Π_{APD} are capable of interpreting the optical densities of motion picture color negative and internegative films as the film manufacturers intended those densities to be interpreted.

Π_{APD} are the appropriate spectral responsivities for scanning devices digitizing motion picture color negative and internegative film imagery for use with the Image Interchange Framework. Its greater currency and unambiguous specification make Π_{APD} a better set of spectral responsivities for a scanning device than the spectral responsivities given in SMPTE RP-180-1999 (Archived 2006) or the unpublished spectral responsivities that were the basis of Eastman Kodak Cineon Printing Density (CPD). APD is directly compatible with contemporary color negative and internegative film stocks, as well as any legacy motion picture color negative and internegative film stocks capable of being printed onto contemporary print films with reasonable results. When appropriately encoded, APD is also compatible with scan-only color negative films, such as Kodak Vision2 HD Color Scan Film (Kodak 5299), even though color negative film stocks of this type are not intended to be directly printable. APD is not appropriate for scanning of color print film material.

The spectral responsivities Π_{APD} provided as part of this specification serves as a reference against which scanning device behaviors can be compared. When a scanning device with spectral responsivities other than Π_{APD} is used to scan a motion picture color negative or internegative film, a stock-specific Input Device Transform (IDT) converts the resulting scanner density values into the APD density values a scanning device with the Π_{APD} spectral responsivities would have produced from that same color negative film (Figure 2).

The purpose of the spectral responsivities Π_{APD} is to provide a well-documented metric for measuring color negative film density values, allowing the unambiguous encoding of those densities in ADX. The encoding of density images in ADX within the Academy Image Interchange Framework allows for the development and use of a universal (i.e. non-stock-specific) transform to convert images encoded in ADX into ACES images.
Figure 2 – Film Scanner Image Processing Diagram

1 Scope

This document specifies ADX, a common RGB density encoding used with the Academy's Image Interchange Framework, and the spectral responsivities used to calculate Academy Printing Density (APD), a common printing density definition which serves as the basis for the encoding method of ADX.

3 Terms and Definitions

The following terms and definitions are used in this document:

3.1   Academy Color Encoding Specification (ACES)

RGB color encoding for exchange of image data that have not been color rendered, between and throughout production and postproduction, within the Academy's Image Interchange Framework.

3.2   Academy Density Exchange Encoding (ADX)

encoding of motion picture film color negative and internegative image data as APD values within the Academy's Image Interchange Framework.

3.3   Academy Printing Density (APD)

printing densities defined by the spectral responsivities Π_{APD}. The spectral responsivities Π_{APD} are defined for use with motion picture color negative and internegative films. APD serves as the basis for the encoding method of ADX, the common densitometric encoding used within the Image Interchange Framework.

3.4   APD film scanner

motion picture film scanning device with spectral responsivities equal to Π_{APD}. An APD film scanner will typically produce ADX encoded image files, as the steps required for encoding are usually accounted for in the scanning process.

3.5   CIE Standard Illuminant A

Planckian radiation at a temperature of about 2,856 K as defined by the Commission Internationale de l'Eclairage (CIE)

3.6   contemporary color negative film

negative color photographic film designed to be printed on Kodak Vision family, Fujifilm Eterna family, and Fujifilm F-CP print films.

3.7   densitometer

device for directly measuring transmission or reflection optical densities. For meaningful color measurements, the illumination and collection geometries and the spectral responses of the densitometer must be specified.

3.8   densitometry

the measurement of optical density.

3.9 D_{min}

optical density of an area of a chemically processed photographic medium that has received zero exposure. D_{min} corresponds to the optical density of film base and non-image density due to factors other than exposure to light.

3.10 equivalent neutral (visual) density (END)

density value used to express the relative amount of subtractive-medium colorants. The END value for a given amount of colorant is the visual density that would result if appropriate amounts of the other colorants of the medium were added such that a colorimetric neutral is formed based on a defined viewing illuminant.

3.11 equivalent neutral printing density (ENPD)

printing density value used to express the relative amount of subtractive-medium colorants. The ENPD value for a given amount of colorant is the printing density that would result if appropriate amounts of the other colorants of the medium were added such that the component printing densities are equal.

3.12 influx spectrum

spectrum of the radiant flux incident on the specimen surface or sampling aperture. It is a function of the energy source and the optical system on the source side of the specimen.

3.13 Input Device Transform (IDT)

color signal-processing transform that maps a device's representation of an image to a common input color encoding specification. ADX is the densitometric input encoding used within the Image Interchange Framework. ACES is the colorimetric input encoding used within the Image Interchange Framework.

3.14 legacy color negative film

negative photographic film designed to be printed on any color print medium other than Kodak Vision family, Fujifilm Eterna family, and Fujifilm F-CP print films.

3.15 negative

photographic medium that forms a reversed image (i.e. higher exposure levels result in the formation of greater optical density during development).

3.16 optical density

negative logarithm to the base 10 of the ratio of the integration of the spectral responsivities of a detection system and the spectral transmittance or reflectance of the sample under examination and the integration of the spectral responsivities of the detection system alone.

3.17 Output Device Transform (ODT)

color signal-processing transform that maps an image represented in a common output color encoding to a representation on a reference device of a particular type.

3.18 print

photographic medium onto which a negative is printed to form a positive image intended for final viewing.

3.19 printing density

optical density measured according to effective spectral responsivities defined by the spectral power distribution of a printer, including the light source, the spectral transmission, reflection and absorbance of its optical components, and the spectral sensitivity of a print medium.

3.20 relative exposure values

relative responses to light of an image capture system determined by the integrated spectral responsitivities of its color channels and the irradiances at the focal plane of the image capture system.

3.21 scan-only color negative film

negative color photographic film primarily designed to be scanned by a motion picture film scanning device rather than printed on any photographic print medium.

3.22 scanner density

logarithm to the base 10 of the ratio of the integration of the spectral responsivities of a scanner and the spectral transmittance of the sample under examination and the integration of the spectral responsivities of the scanner alone.

3.23 silver criterion

principle that each stage of a photographic system shall be maintain equivalent neutral densities or equivalent neutral printing densities for equal red, green, and blue relative exposure values.

3.24 source

physically realizable light, the spectral power distribution of which can be experimentally determined.

3.25 spectral density

optical densities of a medium as measured as a function of wavelength.

3.26 spectral power distribution

power, or relative power, of electromagnetic radiation as a function of wavelength.

3.27 spectral product

wavelength-by-wavelength product of two or more spectral power distributions, spectral sensitivities, spectral responsitivities, or spectral transmittances.

3.28 spectral responsivities

responses of a detection system, such as a scanner or a densitometer, as a function of wavelength. Spectral responsivities are determined by the spectral power distribution of the illumination, the spectral filtration effects of various optical components, and the spectral sensitivity of the detector.

3.29 spectral sensitivity

response of a detector to monochromatic stimuli of equal radiant power.

3.30 spectral transmittance

fraction of the incident power transmitted as a function of wavelength.

3.31 transmittance factor

ratio of the measured flux transmitted by a specimen to the measured flux when the specimen is removed from the sampling aperture of the measuring device.

4   Specification

4.1   Academy Printing Density (APD)

The spectral responsivities associated with any printing density metric are the product of the spectral power distribution of a printer light source, the spectral transmission, reflection, and absorbance of the optical components of the printer, and the spectral sensitivities of the print medium onto which the sample is to be printed. The spectral responsivities used to calculate Academy Printing Density (APD) include the effect of the light source spectral power distribution and the spectral transmission, reflection, absorbance of the optical components of a Bell & Howell Model C printer lamp house, and the spectral transmission of an Eastman Kodak Wratten Filter No. 2B. The spectral sensitivities of the print medium are representative of the spectral sensitivities of contemporary motion picture print films such as those of the Kodak Vision family, of the Fujifilm Eterna family, and of Fujifilm F-CP. The spectral responsivities used to calculate APD, known as Π_{APD}, are illustrated in Figure 3 below.
Figure 3 – The spectral responsivities Π_{APD}

NOTE   Tabulated values of the spectral responsivities Π_{APD}, can be found in Annex A.

4.1.1   Reference Measurement Device

To completely specify a density metric it is necessary to also specify the conditions in which the density measurements shall be made.

NOTE   The specifications in this section are intended to eliminate ambiguity in the determination of the APD values of a film sample. The specifications in this section should not be misconstrued to be specifications for conditions under which films must be scanned. For instance, section 4.1.1.2 specifies that device geometry shall conform to the ISO standard diffuse transmission density. In practice, due to the very low scattering properties of conventionally processed color negative and internegative films, little variation would be expected between scans obtained using a scanner with ISO standard diffuse transmission density geometry and a scanner with ISO standard projection transmission density geometry. Variations that might occur could be compensated for in an IDT.

4.1.1.1 Spectral Responsivities

The reference measurement device shall have spectral responsivities equal to the spectral responsivities $\Pi_{APD.}$

4.1.1.2 Measurement Geometry

The reference measurement device geometry shall conform to the ISO standard diffuse transmission density specification found in ISO 5-2:2001(E).

4.1.1.3 Sample Conditions

Color negative and internegative films to be measured shall be at 23°C ± 2°C (73.4°F ± 3.6°F) and 50% (±5%) relative humidity, consistent with the sample conditions specification for density measurements found in ISO 5-3:1995(E).

4.2 Academy Density Exchange Encoding (ADX)

The Academy Density Exchange Encoding (ADX) encodes densitometric images within the Image Interchange Framework. The ADX equations specified below provide conversions from APD values to digital code values as 10-bit or 16-bit integer color components. ADX images are transformable into ACES using the universal ADX-to-ACES transform. Conversely, ACES images are transformable into ADX images using the universal ACES-to-ADX transform. The universal ADX-to-ACES transform and universal ACES-to-ADX transform are described in other documents detailing the Image Interchange Framework.

4.2.1 Encoding Method

ADX values encode image data as the Academy Printing Density values of a color negative film designed to be printed on Kodak Vision family, Fujifilm Eterna family, and Fujifilm F-CP color print films.

NOTE   Most color negative and internegative films require no transformation in order to be compatible with the ADX encoding method, because most color negative and internegative films can be printed onto contemporary color print films with reasonable results. Color interpositive films are also compatible with the ADX encoding method as they are part of the negative reproduction chain. Some film stocks, such as scan-only color negative film (e.g. Kodak 5299) and color print films, were not designed to be printed onto color print films. Printing a scan-only negative or color print film onto a contemporary color print film is not likely to yield a result that would be considered "good-looking." Scanned density values from these materials require additional transformation in order to achieve compatibility with the ADX encoding method. A custom conversion from scanner density values to ADX must be designed for materials that were not designed to be printed onto color print films.

4.2.1.1 Achieving Encoding Method Compatibility

In order to achieve compatibility with the Image Interchange Framework, color films not capable of being printed onto contemporary color print films with reasonable results shall be scanned temporarily into a set of scanner density values and transformed into a set of ACES values using a film specific transform provided by the film manufacturer. If desired, those ACES values can be transformed into a set of ADX values using the universal ACES-to-ADX transform. The transforms listed above shall be implemented with an Input Device Transform.

4.2.2 Encoding Metric

The encoding data metric for the ADX is based on D_{min} offset Academy Printing Density values. In many cases the D_{min} offset adjustment is accomplished during the setup of the scanning device. In the equations given below APD_{R_Dmin}, APD_{G_Dmin}, and APD_{B_Dmin} represent the red, green, and blue APD values respectively of the assumed or measured D_{min} of the sample.

Two component value encodings are provided. ADX_{16} in which the R, G, and B printing density values are each stored as 16-bit unsigned integers, and ADX_{10} in which the R, G, and B printing density values are each stored as 10-bit unsigned integers.

The exposure of a spectrally nonselective (i.e. neutral color) object by a source for which the film has been balanced, followed by nominal laboratory processing, would ideally produce a negative having equal Red, Green, and Blue printing densities. This ideal behavior, historically present in systems that comply with the silver criterion, is not a characteristic of contemporary motion picture negative films stocks. Encoding gain factors of 1.00, 0.92 and 0.95 in the encoding equations below attempt to produce equality in ADX values for the abovementioned exposure. These gain factors were computed as a weighted average of gain factors for commonly used motion picture films, and will produce ADX values whose corresponding Status M densities are compatible with the capabilities of modern film recorders recording onto intermediate stocks.

NOTE   Printing density values are always non-negative, as a value of 0 represents 100% transmission.

4.2.2.1 ADX_{16} – The 16-bit Component Value Encoding Metric

The ADX 16-bit component value encoding metric shall be known as ADX_{16} or ADX16 where the use of subscripted text is not possible.

The value range for ADX_{16} is [0, 65535].

ADX_{16} code values shall be 16-bit unsigned integer values. An encoding gain of 8000 code values allows for the encoding of a density range of 8.191875 with the density difference between adjacent code values equal to 0.000125. An encoding offset of 1520 code values allows for a density range of 0.190000 below the measured D_{min} to be encoded.

ADX_{16} code values shall be transformed from APD values using Equation (1)..

$$ADX_{16\_R} = \text{INT}\left[1.00 \times \left(APD_R - APD_{R\_Dmin}\right) \times 8000 + 1520\right]$$

$$ADX_{16\_G} = \text{INT}\left[0.92 \times \left(APD_G - APD_{G\_Dmin}\right) \times 8000 + 1520\right]$$

$$ADX_{16\_B} = \text{INT}\left[0.95 \times \left(APD_B - APD_{B\_Dmin}\right) \times 8000 + 1520\right]$$

Equation (1)

NOTE   The INT operator returns the value of 0 for fractional parts in the range of 0 to .4999… and +1 for fractional parts in the range .5 to .9999…, i.e. it rounds up fractions equal to or greater than 0.5.

NOTE 2 The quantity $(APD - APD_{Dmin})$ may produce negative values as the D_{min} value of each color layer can vary throughout a scanned roll. The offset quantity, 1520, provides a target value for the scanned D_{min}, and allows "footroom" so that densities lower than APD_{Dmin} will be encoded.

4.2.2.2   ADX$_{10}$ – The 10-bit Component Value Encoding Metric

The 10-bit component value encoding metric is specified to provide compatibility with existing hardware and file format specifications. Some modern motion picture color negative and internegative film products are capable of producing density ranges that exceed the density range capable of being encoded by the 10-bit component value encoding metric. For this reason, whenever possible the 16-bit component value encoding metric shall be used.

The ADX 10-bit component value encoding metric shall be known as ADX$_{10}$ or ADX10 where the use of subscripted text is not possible.

The value range for ADX$_{10}$ is [0, 1023].

ADX$_{10}$ code values shall be 10-bit unsigned integer values. An encoding gain of 500 code values allows for the encoding of a density range of 2.046000 with the density difference between adjacent code values equal to 0.002000. An encoding offset of 95 code values allows for a density range of 0.190000 below the measured D$_{min}$ to be encoded. ADX$_{10}$ code values shall be transformed from APD values using Equation (2).

$$ADX_{10\_R} = \text{INT}\left[1.00 \times \left(APD_R - APD_{R\_Dmin}\right) \times 500 + 95\right]$$

$$ADX_{10\_G} = \text{INT}\left[0.92 \times \left(APD_G - APD_{G\_Dmin}\right) \times 500 + 95\right]$$

$$ADX_{10\_B} = \text{INT}\left[0.95 \times \left(APD_B - APD_{B\_Dmin}\right) \times 500 + 95\right]$$

Equation (2)

NOTE   The INT operator returns the value of 0 for fractional parts in the range of 0 to .4999… and +1 for fractional parts in the range .5 to .9999…, i.e. it rounds up fractions equal to or greater than 0.5.

NOTE 2 The quantity $(APD - APD_{Dmin})$ may produce negative values as the D$_{min}$ value of each color layer can vary throughout a scanned roll. The offset quantity, 95, provides a target value for the scanned D$_{min}$, and allows 'footroom' so that densities lower than APD_{Dmin} will be encoded.

4.2.2.3   Converting between the 16-bit and 10-bit Component Value Encoding Metrics

The 16-bit Component Value Encoding Metric (i.e. ADX$_{16}$) shall allocate 2 bits of additional range and 4 bits of additional precision as compared to the 10-bit Component Value Encoding Metric (i.e. ADX$_{10}$). The 2 bits of additional range shall be allocated in the most significant bits. The 4 bits of additional precision shall be allocated in the least significant bits. Figure 4 illustrates the allocation of the additional bits in the 16-bit Component Value Encoding Metric as compared to the 10-bit Component Value Encoding Metric.

10-Bit Component Value Encoding Metric

16-Bit Component Value Encoding Metric
Figure 4 – Bit allocations of ADX$_{10}$ and ADX$_{16}$

Equation (3) shall be used to convert APD printing density values encoded using the 10-bit Component Value Encoding Metric to the APD printing density values encoded using the 16-bit Component Value Encoding Metric.

$$ADX_{16} = ADX_{10} \times 16$$

Equation (3)

Equation (4) shall be used to convert APD printing density values encoded using the 16-bit Component Value Encoding Metric to APD printing density values encoded using the 10-bit Component Value Encoding Metric.

$$\text{if FLOOR}[ADX_{16} \div 16] \text{ is even}$$
$$ADX_{10} = \left(ADX_{16} + 7\right) \div 16$$
$$\text{if FLOOR}[ADX_{16} \div 16] \text{ is odd}$$
$$ADX_{10} = \left(ADX_{16} + 8\right) \div 16$$

Equation (4)

NOTE The value of FLOOR[x] is the largest integer that is not greater than x.

The following is an example C programming language code fragment to convert APD printing density values encoded using the 16-bit Component Value Encoding Metric to APD printing density values encoded using the 10-bit Component Value Encoding Metric.

```
int ADX16 = …;
int ADX10 = (ADX16 + 7 + ((ADX16 >> 4) & 1)) >> 4;
```

5 Usage

5.1 Derivation of Π_{APD}

The spectral responsivities defined in this specification are specified as spectral products rather than discrete spectral components. The spectral product for any densitometric specification, film scanner, or densitometer may be denoted using Equation (5).

$$\Pi = S(\lambda)s(\lambda)$$

Equation (5)

where:

$S(\lambda)$ is the relative spectral power distribution of the influx.

$s(\lambda)$ is the relative spectral sensitivity of the receiver, which includes the photodetector and all intervening components between it and the plane of the sample to be measured.

The subscript Π_{APD} shall be used to denote the spectral product representing the spectral responsivities used to calculate APD. Π_{APD_R}, Π_{APD_G}, and Π_{APD_B} shall be used to denote the spectral responsivities of the red, green, and blue components of APD respectively.

The subscript S_{APD} shall be used to denote the relative spectral power distribution of the influx spectrum used in the calculation of the spectral product Π_{APD}.

5.1.1   Influx Spectrum

The spectral responsivities defining APD incorporate the influx spectrum S_{APD}, which models the lamphouse of a Bell & Howell Model C motion picture printer, filtered by an Eastman Kodak Wratten Filter No. 2B.

NOTE   The basic light source for ISO densitometry, as specified in ISO 5-3:1995(E), is CIE Standard Illuminant A. The lamp house of the Bell & Howell Model C motion picture printer uses a tungsten light source that is separated into red, blue, and green components with a set of dichroic mirrors; those components are then modulated by a series of light valves in order to precisely control the ratios of red, green, and blue light, and after modulation are filtered with a Eastman Kodak Wratten Filter No. 2B. Use of S_{APD} in the calculation of the spectral responsivity associated with APD therefore meets the light source requirement of ISO 5-3:1995(E).

NOTE 2 Tabulated values and a graph of the influx spectrum S_{APD} can be found in Annex B.

NOTE 3 The specification of CIE Standard Illuminant A by ISO 5-3:1995(E) is motivated, in part, by the need to manage fluorescence in the sample to be measured.

NOTE 4 Filtration of the light source is permitted and in fact suggested by ISO 5-3:1995(E) in order to protect the sample to be measured and optical elements from the heat of the light source.

5.2 Calculation of APD Values

There are two methods for determining the APD values of color negative and internegative films, as outlined below.

5.2.1   Spectral Calculation

The spectral calculation of Academy Printing Density values requires the measurement of the spectral transmission of the color negative or internegative film using a spectral measurement device. Measured film transmission spectra can be converted into APD values using Equation (6).

$$APD_R = -\log_{10}\left(\int_{360}^{730} T(\lambda)\bar{r}(\lambda)d\lambda\right)$$

$$APD_G = -\log_{10}\left(\int_{360}^{730} T(\lambda)\bar{g}(\lambda)d\lambda\right)$$

$$APD_B = -\log_{10}\left(\int_{360}^{730} T(\lambda)\bar{b}(\lambda)d\lambda\right)$$

Equation (6)

where:

$\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ are Π_{APD_R}, Π_{APD_G}, and Π_{APD_B} normalized such that

$$\int_{360}^{730} \Pi_{APD\_R}(\lambda)\,d\lambda = \int_{360}^{730} \Pi_{APD\_G}(\lambda)\,d\lambda = \int_{360}^{730} \Pi_{APD\_B}(\lambda)\,d\lambda = 1$$

and

$T(\lambda)$ is the spectral transmission of the color negative film or internegative film, or $10^{-density(\lambda)}$

NOTE   In practice, it is common to calculate APD values using summations rather than integrals, as common spectral measurement devices typically return transmission data as a series of spectral samples uniformly separated in wavelength rather than as a single continuous analytic function of wavelength.

NOTE 2 A densitometer with spectral responsivities equal to the spectral responsivities of Π_{APD} could measure APD values directly; no such densitometer, however, exists at the time of this writing.

5.2.2   Conversion from Other Density Metric Values

Conversions between other density metric values (i.e. Status M density, scanner density, etc.) and APD values are possible. These transformations are product specific: a separate transformation needs to be determined for each color negative and internegative film product. The ISO Status M to APD matrix conversion transforms and associated residual errors for a variety of motion picture color negative and internegative films listed in Annex C can be particularly useful in process control efforts. When native scanner spectral responsivities are exactly known, these residual errors may be reduced by substitution of a polynomial conversion transform for the appropriate 3x3 matrix shown below, or by the replacement of that 3x3 matrix by a 3D LUT. Compared to a 3x3 matrix, a polynomial conversion transform may reduce the residual error associated with the conversion between density metrics. Assuming the use of a transform with an appropriate number and distribution of nodes, the use of a stock specific 3D LUT, particularly when used in conjunction with a one or more 1D shaper LUTs, could nearly eliminate the residual errors associated with the transform.

NOTE   Individual densitometers may report optical densities that differ significantly from ISO Status M as specified in the ISO 5 standards. Care should be taken to ensure measurement devices are properly calibrated and report ISO Status M density values for a known sample. For instance, the density values of the transmission tablet used to calibrate the X-Rite® 310 transmission densitometer are reported as densities that conform to ANSI PH2.19-1976 rather than ANSI PH2.19-1986 and ISO 5. Instructions are included with the calibration tablet in order to calibrate the device to ISO Status M rather than ANSI PH2.19-1976 and care should be take to ensure the device is calibrated to the ISO Status M standard.

NOTE 2 Film scanners typically are not manufactured with spectral responsivities that either match, or are a linear combination of ISO Status M. However, if a film scanner exhibits spectral responsivities that match ISO Status M, the transforms in Annex C may be used to transform the scanner density values into APD. If a film scanner exhibits spectral responsivities that are a linear combination of ISO Status M responsivities, a 3x3 transform may be used to convert the scanner density values into ISO Status M before using the transforms in Annex C. If a film scanner does not exhibit spectral responsivities that either match, or are a linear combination of ISO Status M responsivities, either a more complex transform to convert scanner density values to ISO Status M density values must be used before the transforms in Annex C, or the transforms in Annex C are not appropriate for conversion of those scanner density values into APD and a different set of stock-specific scanner density to APD IDTs must be calculated. Procedures for characterizing a scanner with spectral responsivities other than those of ISO Status M or a linear combination of ISO Status M responsivities, and the calculation of appropriate IDTs, are described in other documents detailing the Image Interchange Framework.

Annex A

(normative)

Spectral Responsivities Π_{APD}

The spectral responsivities used to determine Academy Printing Density are the spectral product (Π_{APD}) of the relative spectral power distribution of the influx (S_{APD}) and the relative spectral response of the receiver (s), which includes the photodetector and all intervening components between it and the plane of the sample to be measured.

The relative spectral power distribution of the influx spectrum S_{APD} is illustrated in Figure 5 below. The influx spectrum is normalized to 1.0 at 560nm.

Figure 5 – Influx Spectrum S_{APD}

Annex C

(informative)

Status M to APD Conversion Transforms

Listed below are sample ISO Status M to APD conversion transforms and the associated residual errors for a variety of motion picture color negative and internegative films. The matrix coefficients were computed based on spectral measurements of 31 contemporary camera negative and intermediate film stocks. A set of test patches, consisting of 33 "grays" (a ramp of approximately equal Status M densities in all three dyes) and 64 "colors" (a cube of 43 approximately equidistant density combinations), was exposed on each film stock. An ARRILASER film recorder was used to create the test negatives. The resulting 97 patches on each negative were measured with a spectrophotometer in 10 nm increments. The spectral transmission of each measured patch was converted to Status M density and APD, respectively. A least-squares regression was used to calculate the Status M density to APD transforms listed below. The associated residual errors are listed in the table below each transform.

The most likely use for the Status M to APD transforms below is process control. In those circumstances, a density ramp is produced on a negative. The negative is measured with a densitometer and the resulting Status M values are converted to APD. With the exception of the intermediate stocks, the expected errors are all smaller than or equal to 0.02. For the intermediate stocks or in other cases where a higher accuracy of the conversion is desired, a polynomial conversion or a 3D LUT may be calculated.

The following is a description of the residual error statistics calculated and reported in each table.

mean abs error (all)

The arithmetic mean of the absolute differences between the fitted and the measured APD values used in the regression.

max abs error (all)

The maximum of the absolute differences between the fitted and the measured APD values used in the regression.

max abs error (gray)

The maximum of the absolute differences between the fitted and the measured APD values of the "gray" values only. Those errors are considered to be most relevant in applications where the matrices are used for process control.

max abs error (Macbeth)

The maximum of the absolute differences between the fitted and the measured APD values for an independent set of 18 colors similar to the ones used in the Macbeth ColorChecker.

max abs error (large)

The maximum of the absolute differences between the fitted and the measured APD values for a large set of patches consisting of 33 "grays" and an independent set of 216 "colors". This test was done to ensure that the calculated transformations are not too dependent on the regression samples.

NOTE   The transforms given below were calculated from the spectral transmission measurements of a particular set of patches using a particular regression methodology to calculate the transform coefficients. If a different set of patches or a different regression routine were used, the transform coefficients and residual errors calculated would be slightly different than those given above. For details contact the Academy at councilinfo@oscars.org.
